Keywords: osteocyte; isolation; age; culture; collagenase; mice

The purpose of this work was to establish a methodology to enable the isolation and study of osteocytes from skeletally mature young (4-month-old) and old (22-month-old) mice. The location of osteocytes deep within bone is ideal for their function as mechanosensors. However, this location makes the observation and study of osteocytes in vivo technically difficult. Osteocytes were isolated from murine long bones through a process of extended collagenase digestions combined with EDTA-based decalcification. A tissue homogenizer was used to reduce the remaining bone fragments to a suspension of bone particles, which were placed in culture to yield an outgrowth of osteocyte-like cells. All of the cells obtained from this outgrowth that displayed an osteocyte-like morphology stained positive for the osteocyte marker E11/GP38. The osteocyte phenotype was further confirmed by a lack of staining for alkaline phosphatase and the absence of collagen1a1 expression. The outgrowth of osteocytes also expressed additional osteocyte-specific genes such as Sost and Mepe. This technique facilitates the isolation of osteocytes from skeletally mature bone. This novel enabling methodology should prove useful in advancing our understanding of the roles mature osteocytes play in bone health and disease.

The coordinated actions of three different types of bone cells are required for bone remodeling in response to mechanical loading. On the surface of bone are osteoblasts, which form new bone, and osteoclasts, which remove bone. Located deeper within the bone matrix and housed in cave-like lacunae, are osteocytes, which function as the mechanosensory system within bone. Osteocytes have a dendritic morphology with many cell processes extending through canaliculi to form a highly connected communication network between themselves and the bone surface cells. When mechanical loads are applied to bone, they are sensed by osteocytes, which translate signals provided by mechanostimulation into biochemical signals. These signals are believed to regulate the actions of osteoblasts and osteoclasts, thereby providing a mechanism to regulate bone deposition and absorption according to the local mechanical requirements of the bone (1–3).

Osteocytes are the most abundant of the three bone cell types; however, the least is known about them. While their location deep within the bone matrix makes them ideally situated to sense bone strain, it also makes their observation and study in vivo difficult. Additionally, primary osteocytes, particularly those within the long bones of skeletally mature animals, have proven difficult to obtain and study ex vivo. Furthermore, once primary osteocytes are obtained, their study is often limited by their inability to proliferate as they are considered terminally differentiated cells.

To facilitate the study of osteocytes in vitro, Kato et al. created the immortalized osteocyte-like MLO-Y4 line from osteocytes isolated from the long bones of 6-week-old transgenic mice, in which the SV40 large T-antigen oncogene is expressed under the control of an osteocalcin promoter (4,5). The MLO-Y4 cell line has characteristics of a postosteoblast/preosteocyte. These cells are very large, over 100 nm, express all of the markers of the late osteoblast such as osteocalcin, and rapidly mineralize in sheets, not nodules (30). In culture, these cells begin to express markers of osteocytes as they generate cell processes such as E11 (31), but also express low levels of Sost.

Supplementary material for this article is available at www.BioTechniques.com/article/113876
Recently, a cell line has been generated that differentiates from the late osteoblast to the late osteocyte called IDG-SW3, made by crossing the Immortomouse with the 8-kb Dmp1-GFP transgenic mouse line. IDG-SW3 cells synthesize and mineralize a “honeycomb-like” matrix rich in type-I collagen similar to MLO-A5 cells. Similar to osteocytes in vivo, these cells express osteocyte marker genes from the early osteocyte marker E11 to the mature osteocyte marker sclerostin, down-regulate Sost expression with PTH treatment and increase Fg f23 mRNA expression in response 1,25-dihydroxyvitamin D3 (32). This cell line faithfully recapitulates the differentiation process from osteoblast to late osteocyte as observed in vivo.

While these cell lines are convenient and useful, an ideal strategy for the study of osteocyte function ex vivo, and validation of results obtained with cell lines is to develop better methodology for the isolation and study of primary osteocytes.

Primary osteocytes have most commonly been isolated from 16- or 18-day-old chick calvaria (15,33–44) or from newborn through 4-day-old rat calvaria, 12-day-old mouse calvaria (45), and 3- to 4-week-old mouse calvaria and long bones (46). More recently, osteocytes have also been isolated from the long bones of 3-day-old Sprague-Dawley rats (33). Calvaria from young chicks and neonatal rats and mice, as well as the long bones from neonatal rats and young mice (3–4 weeks) are all very thin and easily processed using sequential digestions with EDTA and collagenase. Studies utilizing these primary osteocytes can provide insight to the behavior of osteocytes during development but do not aid in the study of osteocytes from skeletally mature animals or enable the comparison between osteocytes isolated from skeletally mature but relatively less mature animals.

Figure 1. Total number of cells and percentage of viable cells obtained at each stage of digestion during osteocyte isolation. (A) Total number of cells obtained from the combined long bones of a single mouse during each stage of digestion from the long bones of a single mouse. (B) The percentage of viable cells isolated during each stage of digestion based on trypan blue staining (n = 4 for both the 4-month-old and 22-month-old mice).

Figure 2. Primary osteocytes display an osteocyte-like morphology and express E11/GP38. After 7 days in culture, a majority of the (A and B) young and (C and D) old cells from the bone particle outgrowth displaying an osteocyte-like morphology also stained positive for E11/GP38 (green). (E and F) MLO-Y4 osteocyte-like cells were used as a positive control for the E11/GP38 staining. DAPI (blue) stain was utilized to identify cell nuclei and count cells. Phase-contrast images of the same fields (C and D) are shown for comparison (magnification = 200x in all images).
Materials and methods

Primary osteocyte isolation

Osteocytes were isolated from mouse long bones utilizing a modified protocol derived from the combined methods of Gu et al. and Van Der Plas et al. (33,44,47). Long bones (femurs, tibiae, and humeri) were aseptically dissected from skeletally mature young mice (4- to 6-month) and aged mice (>22-month-old).

The purpose of the work presented here was to create an osteocyte isolation technique to enable the isolation and study of osteocytes from the long bones of young mature and old adult mice.

RT-PCR was performed for genes expressed in osteocytes using Taqman Gene Expression Assys primers (Applied Biosystems, Foster City, CA, USA).

Primary bone cell culture

Cell suspensions resulting from the primary isolation procedure (detailed in section above) were cultured on type-1 rat tail collagen-coated six-well plates (Becton Dickinson, Franklin Lakes, NJ, USA) at a seeding density of approximately 250,000 cells per 9.5 cm² in α-minimal essential medium (αMEM; Mediatech) supplemented with 5% fetal bovine serum (FBS; Summit Biotechnology, Fort Collins, CO, USA), 5% calf serum (CS; HyClone Laboratories, Logan, UT, USA), and 1% penicillin and streptomycin (PS; Cellgro, Manassas, VA, USA). Cells were maintained at 37°C and 5% CO₂, humidified incubator for 7 days.

Culture of MLO-Y4 cells

MLO-Y4 cells, a murine osteocyte-like immortalized cell line, were utilized as control cells in these experiments (4,5). They were cultured on type-I rat tail collagen-coated tissue culture plates in α-MEM supplemented with 2.5% FBS, 2.5% CS, and 1% PS. The cells were maintained in a 37°C and 5% CO₂ humidified incubator and subcultured approximately every 72 h to maintain the cell populations at least 70% confluent.

Culture and differentiation of MC3T3-E1 cells

The MC3T3-E1 cell line (subclone 4; ATCC, Manassas, VA, USA) was also utilized as control cells in these experiments. They exhibit markers of osteoblast differentiation, particularly expression of ALP after growth in ascorbic acid and phosphate, but prior to differentiation do not express ALP. MC3T3-E1 cells were cultured on type-I rat tail collagen-coated tissue culture plates in α-MEM, supplemented with 10%...
FBS, 1% PS. To induce osteogenic differentiation, 50 µg/mL ascorbic acid and 10 mM β-glycerophosphate were added to the culture media. The cells were allowed to differentiate for 14 days, changing the media as needed.

Culture of SW3 cells
The IDG-SW3 cell line were utilized as control cells for investigating osteocyte marker expression as these cells have previously been shown to express mature osteocyte markers, such as Mepe, Sost, and Fgf23, when differentiated (32). Cells were cultured in α-MEM, supplemented with 10% FBS, 1% PS, and 50 U/mL interferon-γ (IFN-γ; Invitrogen, Carlsbad, CA, USA), to induce proliferation. Upon reaching confluence, the media was replaced with differentiation media, containing α-MEM, 10% FBS, 1% PS, 50 µg/mL ascorbic acid, and 4 mM β-glycerophosphate, to induce osteogenic differentiation. The media was replaced every 3 days, and the cells were differentiated for 21 days.

Viable cell counts
Following each digestion, cells were counted using a hemocytometer before being plated. A trypan blue (MP Biomedicals, Solon, OH, USA) exclusion test for cell viability was utilized to determine the number of dead cells in each of the cell isolations. The percentage of viable cells was calculated for each digestion for cell isolations from both the young and old bones.

Immunostaining for E11/gp38
Primary osteocytes isolated from 4- and 22-month-old mice were immunologically identified using an anti-E11/GP38 antibody 7 days following the isolation procedure. In osteocytes, E11 has been...
shown to be responsible for dendrite elongation and is a marker of early osteocytes. The bone cells isolated from the young and old bone particles at 7 days post-isolation, and control MLO-Y4 cells were fixed with 4% paraformaldehyde in PBS for 10 min, then incubated with PBS for 2 min. The cells were then incubated for 45 min at 25°C with gentle shaking with blocking solution: PBS + 10% goat serum (HyClone Laboratories). Primary antibody, podoplanin (8.1.1; Santa Cruz Biotechnology, Santa Cruz, CA, USA) at a 1:50 dilution, was applied in PBS + 3% goat serum overnight at 4°C with shaking. After washing with PBS, the secondary antibody-Alexa Fluor 488–labeled goat anti-hamster IgG (Molecular Probes, Eugene, OR, USA) at 10 µg/mL was applied for 45 min with gentle shaking. Cells were then washed with PBS, counterstained with 4′,6-diamidino-2-phenylindole (DAPI; Vector, Burlingame, CA, USA), and mounted prior to imaging by fluorescence microscopy. The percentage of osteocytes within the cell isolates was quantified by determining the percentage of E11/GP38+ cells present using DAPI to quantify the total number of cells. A total of 10 random fields of each isolate were counted at 200× magnification.

**ALP staining**

ALP staining was conducted on the cell populations isolated from the outgrowth of cells from the bone particles for young (4-month-old) and old (22-month-old) murine long bones 7 days post-isolation. The media was removed and the cells washed with DPBS, fixed with 4% paraformaldehyde for 2 min, rinsed with DPBS, and then incubated at ambient temperature on a shaker with ALP staining solution for 30 min. A 25-mL formulation of the staining solution consisted of 24 mL MilliQ water, 1 mL Napthol AS-MX phosphate alkaline solution–0.25% (Sigma-Aldrich), and 25 mg Fast Violet B salts (Sigma-Aldrich). The ALP staining solution was removed and cells were coverslipped. For each cell population, 10 random fields were imaged at 200× magnification. Fibroblast-like (ALP-negative elongated spindle-shaped cells), osteoblast-like (ALP-positive and cuboidal in shape), and osteocyte-like (ALP-negative or only weakly positive stellate cells) cell fractions were quantified for the osteocyte-enriched cell populations isolated from the final bone particle digestion for the bones isolated from young (4-month-old) and old (22-month-old) mice. MLO-Y4 cells, undifferentiated MC3T3-E1 cells, and differentiated MC3T3-E1 cells were also stained at the same time and used as controls.

**Col1a1 DsRed mouse cell isolation**

The osteocyte isolation procedure was utilized to procure cells from collagen DsRed mice (generously provided by Dr. David Rowe, University of Connecticut Health Center) \( (n = 2, \text{ age } = 4 \text{ months}) \). These mice express the DsRed reporter gene under control of the murine 3.6-kb Col1a1 promoter. Cells expressing COL1A1, a marker of osteoblasts, can be positively identified by their DsRed reporter activity and distinguished from mature osteocytes, which are negative for COL1A1 expression. Seven days post-isolation, the cell populations from the final digestion and those from the bone particle outgrowth were analyzed. Bright field and fluorescent images were captured at 100× magnification. A total of five fields were randomly imaged per digestion, and the percentage of DsRed-positive cells was calculated. Cells isolated from the early digests were used as a positive control, as these are the osteoblast-enriched digestions (33).

**Gene expression**

Seven days post-isolation, RNA was isolated from the outgrowth of cells from the fine

![Image](www.cosmobiousa.com)
bone particle digestion as well as the plated cells from digest 9 in both the young and old isolations using the RNeasy Plus mini kit (Qiagen, Valencia, CA, USA) and reverse-transcribed using the SuperScript III First-Strand Synthesis SuperMix for qRT-PCR (Invitrogen). Reactions lacking RT, bone lysate from both young and old bones, and SW3 cells were utilized as controls. The bone lysate was derived from the bone particles obtained from the tissue homogenizer in the final stage of the cell isolation process. RT-PCR was performed for the following osteogenic genes: E11, Sost, Fg23, Cox2, Mepe, Phex, and Dmp1 using commercially available primers (Table 2). β2m was used as the endogenous control. RT-PCR products were visualized on a 1% agarose gel stained with ethydium bromide with a 100–1000 base pair ladder used for reference (Bio-Rad Laboratories, Hercules, CA, USA).

### Results and discussion

The isolation procedure (described in primary osteocyte isolation section of Materials and methods) results in a highly osteocyte-enriched population of primary cells within the final digestion as well as from the outgrowth of additional cells from the bone particles obtained during processing in the tissue homogenizer. The isolated cells exhibited the classic osteocyte morphology with long dendritic cell processes projecting away from the cell body and had an osteocyte-like phenotype.

#### Viable cell counts

To determine how many cells could be obtained per mouse and if the cells survived the isolation procedure, the number and viability of the cells was examined following each stage of the process. There was a large variation in the number of cells isolated during the initial digestions, but the later digestions consistently produced around 250,000 cells per digestion per mouse (Figure 1). Approximately 90% of the cells in each digestion were viable based on trypan blue staining.

### E11/GP38 staining

E11/GP38 is the earliest osteocyte-specific protein to be expressed as the osteoblast differentiates into an osteocyte (9). To determine what percentage of cells obtained during the final stage of the isolation procedure expressed E11/GP38, immunofluorescent staining was used. After 7 days in culture, the outgrowth of cells from the final bone particles (after all nine stages of digestion and processing in tissue homogenizer) of young (4-month-old) and old (22-month-old) mice were fixed, immunofluorescently stained, and imaged. In the outgrowth of cells from both the young and old bone particles, 100% of the isolated cells that displayed an osteocyte-like morphology also positive for E11/GP38, thereby confirming the osteocyte phenotype (Figure 2). E11/GP38 is also highly expressed in MLO-Y4 osteocyte-like cells, which were used as a positive control for E11/GP38 staining (6). A negative control further confirmed the specificity of the antibody (data not shown). Cells from the early stages of the digestions (digests 4 and 5) were also plated and stained. Approximately 50% of these cells stained positive for E11/GP38 (data not shown).

### ALP staining

ALP expression and activity is an indicator of the osteoblastic state and its expression is shut down in osteocytes. To determine what percentage of cells obtained during each stage of the isolation procedure express ALP, a colorimetric assay for ALP expression was performed. The percentage of osteocyte-like cells obtained during each of the digestes, based on the lack of ALP staining and a stellate/dendritic morphology, increased with each sequential digestion (Table 3). The highest percentage of osteocyte-like cells was found in the outgrowth of cells from the bone particles that remained after the final digestion and processing in the tissue homogenizer (Figure 3).

### COL1A1 DsRed mouse cell isolation

Collagen type-I is a major component of bone and produced by osteoblasts. To determine if cells obtained during the isolation procedure...
were collagen I–producing osteoblasts, the osteocyte isolation was carried out on the bones of mice carrying a DsRed reporter gene under control of the murine 3.6-kb Col1a1 promoter, and the percentage of DsRed positive cells obtained at each stage of the procedure was determined via fluorescent microscopy. After 7 days in culture, a total of five fields were randomly imaged per stage of digestion resulting in an average of 250 cells per digestion (Figure 4). The percent of cells expressing DsRed was highest in the cells obtained in digests 3–5 and decreased in the later digestions (Figure 5), suggesting that early and middle fractions were the most enriched for osteoblasts, while late fractions contained relatively few osteoblasts.

**Gene expression**

Osteocytes are known to express several genes that are both important for their function and can distinguish them from other bone cells. Osseoid osteocytes are known to express E11, Fgf23, and Mepe, while mineralizing osteocytes express Dmp1, and mature osteocytes encased in a mineralized matrix express Sost and Fg/23 (1). In osteocytes, COX2 is known to play a role in the regulation PGE2 (prostaglandin E2) production (6). To determine if cells isolated using the methodology described above possess a gene expression profile characteristic of osteocytes, RT-PCR was performed. In the harvest of bone cells from both young and old mice, cells within digest 9, as well as the outgrowth of cells from homogenized bone particles, expressed several genes characteristic of osteocytes, RT-PCR was performed. In the harvest of bone cells from both young and old mice, cells within digest 9, as well as the outgrowth of cells from homogenized bone particles, expressed several genes characteristic of osteocytes, including: E11, Sost, Cox2, Mepe, PheX, and Dmp1 (Figure 6). Total bone lysate and the SW3 cell line (32) were used as positive controls. As can be seen, all genes were expressed to various levels in young mouse bone lysate, old mouse bone lysate, and SW3 cells. The young mouse digest 9 gene expression profile was very similar to the young mouse cells from particles. However, there was less Fg/23 in digest 9 compared with the cells from the particles. The old mouse digest 9 was very similar to old mouse cells from particles where no Fg/23 was detected. Although there appeared to be lower expression of PheX in the old mouse cells from particles, these experiments would have to be performed in triplicate to determine if significant differences exist.

In this study, we were able to successfully isolate primary cells displaying several characteristics of osteocytes from the long bones of skeletally mature 4-month-old and 22-month-old mice through a process of sequential digestions and the use of a tissue homogenizer. From both the 4-month-old and 22-month-old mice, approximately 250,000 cells per osteocyte-enriched digestion (digestions 7–9) were obtained. These cells expressed E11/GP38 protein, and they lacked ALP and COL1A1 expression found in osteoblasts. Furthermore, several genes known to be expressed in osteocytes were also expressed in the cells obtained using our methodology. These include E11/gp38, Sost, Cox2, Mepe, PheX, and Dmp1. While Fg/23 expression was not detected in cells within digest 9 from young and old mice or the outgrowth of cells from homogenized bone particles from old mice, it was highly expressed in the total bone lysate and SW3 controls and faintly in the outgrowth of cells from homogenized young bone particles. Fg/23 expression is down-regulated by DMP1 and PHEX and up-regulated by MEPE, 1,25-dihydroxyvitamin D3, and PTH by unknown mechanisms (48,49). In IDG-SW3 cells, Fg/23 expression was detected after 2 weeks in culture under mineralizing conditions, therefore it appears to be a late expression gene (32). Therefore, this gene may be more quickly lost upon isolation and culture.

A limitation of our gene expression results is that they are representative of the total population of cells obtained during each stage of the procedure and not individual cells. Therefore, it remains possible that not all of the E11/GP38 expressing cells (nearly 100% of the cells obtained during the final stages of the procedure) express each of the genes listed above. In fact, this would be expected, as the procedure should lead to the isolation of both early and late osteocytes, which are known to differ in Dmp1 and Sost expression in vivo. Thus, a limitation of the procedure is that a mixed population of cells is obtained during each digest; however, this is a common problem with the use of primary cells and certainly not unique to isolating osteocytes.

This isolation technique can be used in a number of ways. By combining our osteocyte isolation procedure with fluorescence-activated cell sorting (FACS) to sort pure populations of both early and late osteocytes, which are known to differ in Dmp1 and Sost expression in vivo. Thus, a limitation of the procedure is that a mixed population of cells is obtained during each digest; however, this is a common problem with the use of primary cells and certainly not unique to isolating osteocytes.
